

The small world effect on the Rio de Janeiro's mobility complex network

Leonardo Bacelar Lima Santos e Antônio Miguel Vieira Monteiro

The structures of urban mobility can be analyzed using different types of (complex) networks. These networks can be built using actual data about number of people traveling from a traffic zone to another (from one vertex to another) as the control parameter (for edges creation). For an appropriate set of this threshold, the topological properties of networks reveal a small world effect.
